1  
2  
3 Nest site selection is critical for social insects since poor choices can heighten predation risks  
4 and result in reproductive failure (Franks *et al.* 2002). Social bees vary in their nest site  
5 requirements and among the *Apis* bees in south Asia, *Apis dorsata* and *A. florea* nest in open  
6 combs, whereas *Apis cerana* nests in cavities (Crane 1999). *Apis dorsata* often nests in  
7 aggregations, and the large open nests can be about 1.5 m wide and are located in sites such as  
8 cliff faces or on the underside of branches of tall trees that are inaccessible to most predators  
9 except skilled fliers and climbers (Crane 1999, Seeley *et al.* 1982). *Apis dorsata*, which is widely  
10 distributed in tropical and subtropical Asia, is an important source of honey and wax for local  
11 communities, and understanding its nesting biology would help in the management and  
12 conservation of this economically important species.

27 We surveyed trees occupied by *Apis dorsata* nests in two sites in the Nilgiri Biosphere  
28 Reserve in the Western Ghats of India, within the major flowering season in both forests  
29 (unpublished data), and prior to the annual migration of *A. dorsata* in late June-July, during the  
30 south-west monsoon. The sites were Appankappu in the wetter Nilambur region of Kerala  
31 (latitude 11°27'N, longitude 76°17'E, altitude 300m asl), which is covered with degraded wet  
32 evergreen forests, and Bedaguli (latitude 11°49'N, longitude 77° 11'E, altitude 1355m asl) in the  
33 Chamraj Nagar region of Tamilnadu, which has moderately disturbed semi-evergreen forests and  
34 grasslands. Appankappu was surveyed in April 2008 and Bedaguli in May 2008. We tested the  
35 null hypothesis that nests of *A. dorsata* were randomly located with regard to tree species, tree  
36 height, girth and bark texture.

50 We used data from 100 plots of 10 × 10 m covering a total area of 1 ha in each study site.  
51 The plots were randomly placed in the forests at different distances and different directions from  
52 the focal villages of Appankappu and Bedaguli, over a radius of approximately 2-4 km. Within  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 plots, all trees and lianas  $\geq 10$  cm dbh were measured at 1.3 m above ground level, and in trees  
4  
5 with buttresses, the measurements were taken above the buttresses. The height (m) was measured  
6  
7 using a clinometer. Inventoried plants were identified to species whenever possible. The canopy  
8  
9 cover of each plot was measured using a densitometer and percentage values were arcsine  
10  
11 transformed for analysis. Each  $10 \times 10$ -m plot was intensively searched for a colony of *A.*  
12  
13 *dorsata* with the help of local indigenous honey hunters. If the nest was observed, the species of  
14  
15 tree was identified. To see whether the colony sizes differed between sites, the distribution of  
16  
17 nests per tree was tested using a Kolgomorov-Smirnov test.

18  
19  
20  
21  
22 To see whether nests were located predominantly on large trees, the dbh (cm) and heights  
23  
24 of trees (m) with and without nests was correlated for each site. A curve was fitted to see  
25  
26 whether the sizes of nesting trees were larger than the average sizes of trees in each site. Only  
27  
28 trees above the minimum height of *Apis dorsata* nesting trees in each site were used in the  
29  
30 analysis. The data were transformed, if necessary, to normalise the distribution. A logistic  
31  
32 regression was used to see whether tree cover (arcsine proportion) in each of the  $10 \times 10$ -m plots  
33  
34 was associated with the likelihood of hosting nests. Data from both sites were pooled for the  
35  
36 analysis.

37  
38  
39  
40  
41 The tree species with and without *Apis dorsata* nests was listed for each site. To see  
42  
43 whether nests were disproportionately located on more abundant tree species, we selected  
44  
45 species that occurred at densities  $\geq 10 \text{ ha}^{-1}$ , and were within the range of heights of *A. dorsata*  
46  
47 nesting trees. The relationship between density of these trees and the probability of hosting nests  
48  
49 were tested using Spearman rank correlation. The bark characteristics of each tree was assessed  
50  
51 using floras (Gamble 1935, Matthew 1983) and by personal observation and classified as 'rough'  
52  
53 or 'smooth'. A  $\chi^2$  test was used to see whether there was an association between bark  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 characteristics and the probability of hosting *A. dorsata* nests. Systat (2000) was used for the  
4  
5 statistical tests.  
6  
7

8 The forest at Bedaguli was more diverse and dense with significantly more individuals  
9  
10 (mean plants  $\pm$  SD, Appankappu =  $7.5 \pm 3$ , Bedaguli =  $15 \pm 4$ , t test,  $t = 3.66$ ,  $df = 190$ ,  $p < 0.0001$ ) and  
11  
12 species (mean species  $\pm$  SD, Appankappu =  $5.5 \pm 2$ , Bedaguli =  $7.8 \pm 3$ , t test,  $t = 6.68$ ,  $df = 184$ ,  
13  
14  $p < 0.0001$ ) per plot than in Appankappu. The trees were significantly taller in Appankappu (mean  
15  
16 height (m)  $\pm$  SD, Appankappu =  $17 \pm 4$ , Bedaguli =  $15 \pm 4$ , t test,  $t = 3.66$ ,  $df = 190$ ,  $p < 0.001$ ).  
17  
18 However, the density of *Apis dorsata* nests per plot did not differ significantly (mean number of  
19  
20 nests  $\pm$  SD, Appankappu =  $0.26 \pm 1.3$ , Bedaguli =  $0.34 \pm 1.3$ , t test,  $t = -0.44$ ,  $df = 190$ , ns). The  
21  
22 distribution of colonies among trees did not significantly differ between sites (Kolmogorov-  
23  
24 Smirnov two-tailed test,  $k = 0.19$ , ns).  
25  
26  
27  
28

29 In Appankappu, 1060 trees and lianas from 90 species were inventoried and 24 nests  
30  
31 were recorded on 11 trees belonging to six species. The shortest nesting tree was 20m tall. A  
32  
33 single *Tetrameles nudiflora*, which was the tallest tree (40 m) in the site, hosted 11 nests whereas  
34  
35 eight of the nests were solitary. In Bedaguli, 1439 trees and lianas from 99 species were recorded  
36  
37 and of these 16 trees from 11 species hosted 46 nests. A single 25-m-tall wild *Mangifera indica*  
38  
39 tree hosted 10 nests. The shortest nesting tree in Bedaguli was 18m tall.  
40  
41  
42

43 The heights of trees in Appankappu (Wilks-Shapiro test = 0.97, ns) and in Bedaguli  
44  
45 (Wilks-Shapiro test = 0.97, ns) did not significantly differ from a normal distribution, dbh values  
46  
47 were skewed and were  $\log_2$ -transformed to normalise the distribution.  
48  
49

50 The mean ( $\pm$  SD) heights of nesting trees ( $34 \pm 6$  m) differed significantly from that of  
51  
52 non-nesting trees in Appankappu (non-nesting trees:  $12.8 \pm 8$  m; t test:  $t = 13.7$ ,  $df = 1058$ ,  $P <$   
53  
54  $0.0001$ ) and Bedaguli (nesting trees:  $28.5 \pm 4$  m; non-nesting trees:  $15 \pm 5$  m, t test:  $t = 15.7$ ,  $df$   
55  
56  
57  
58  
59  
60

1  
2  
3 =1448,  $P < 0.0001$ ). The mean ( $\pm$  SD)  $\log_2$  dbh values also significantly differed (Appankappu:  
4 Nesting trees,  $139 \pm 42$  cm; Non-nesting trees,  $21 \pm 24$  cm, t test:  $t = 10.9$ ,  $df = 1058$ ,  $P < 0.0001$ .  
5  
6 Bedaguli: Nesting trees,  $125 \pm 29$  cm; Non-nesting trees,  $29 \pm 20$  cm, t test:  $t = 15.7$ ,  $df = 1448$ ,  $P$   
7  
8  $< 0.0001$ ). Figure 1 indicates that nesting trees in both sites were larger than the standard sizes of  
9  
10 trees in each site.  
11  
12  
13

14  
15 There was no correlation between the densities of nesting and non-nesting tree species  
16 ( $\geq 10 \text{ ha}^{-1}$ ) in Appankappu (Spearman rank correlation  $r_s = -0.17$ ,  $n = 24$ , ns), indicating that nest  
17 location was not related to the local abundance of species, whereas there was a significant  
18  
19 negative correlation between the densities of nesting and non-nesting tree species ( $\geq 10 \text{ ha}^{-1}$ ) in  
20  
21 Bedaguli (Spearman rank correlation  $r_s = -0.70$ ,  $n = 22$ ,  $P < 0.001$ ), suggesting that the nesting  
22  
23 tree species were uncommon in the site. The occurrence of *Apis dorsata* nests in the  $10 \times 10$ -m  
24  
25 plots was negatively related to tree canopy cover (Log likelihood ratio = -62.0;  $y = 0.77 - 2.92x$ ,  
26  
27 t-ratio = -2.89,  $P = 0.004$ ), suggesting that the nests were located on trees within plots with more  
28  
29 open canopies.  
30  
31  
32  
33  
34  
35

36  
37 In all we listed 16 nesting and 15 non-nesting trees from both sites. The non-nesting trees  
38 were tall ( $\geq 20$  m in Appankappu and  $\geq 18$  m in Bedaguli) and common (densities  $\geq 10 \text{ trees ha}^{-1}$ ).  
39  
40 Fourteen species had smooth bark and 17, rough bark (Table 1). There was no association  
41  
42 between the bark characteristics of nesting and non-nesting trees ( $\chi^2 = 1.64$ ,  $df = 1$ , ns). The trees  
43  
44 belonging to the family Combretaceae did not host nests whereas *Ficus* trees appear to be  
45  
46 preferred (Table 1).  
47  
48  
49  
50

51  
52 Our study shows that *Apis dorsata* nests were preferentially located on trees that were  
53  
54 larger than average in two sites in the Nilgiri Biosphere Reserve, and were more isolated than the  
55  
56 other trees. However, there was no clear preferences based on taxonomic criteria or bark  
57  
58  
59  
60

1  
2  
3 characteristics, although families such as the Combretaceae which tend to have a rough or  
4  
5 peeling bark did not host a single nest. This supports that observation of Seeley *et al.* (1982) in  
6  
7 Thailand that *A. dorsata* nested at heights of about 18 m on tall trees of particular families that  
8  
9 did not branch for about 13 m. Tree architectural features such as spreading branches can  
10  
11 increase the space for more nests to congregate; bark texture, especially smooth bark, seems also  
12  
13 to be important criteria for nest site selection, although there was no trend in our database. This  
14  
15 suggests that structural features and tree isolation, which probably ensured protection against  
16  
17 predators, were the primary criterion used for locating nests. *Apis dorsata* nests face a range of  
18  
19 predators, from birds to bears and humans (Crane 1999, Seeley *et al.* 1982) and therefore nest  
20  
21 location is crucial for the survival of colonies. Our findings, indicating the importance of  
22  
23 particular nesting trees, may have profound implications for the conservation and management of  
24  
25 *A. dorsata* at the landscape scale. *Apis dorsata* colonies migrate over distances of 100 km  
26  
27 (Koeniger & Koeniger 1980) and return to their original nest site (Paar *et al.* 2000). Particular  
28  
29 nesting sites such as large trees and cliffs are used year after year, and the loss of such trees and  
30  
31 cliff faces may limit nest densities in the wild. Tall trees are more frequent in primary unlogged  
32  
33 forests and intensive logging over the geographical range of *A. dorsata* in Asia removes many  
34  
35 potential nesting sites (Laurance 2007).

Sterculiaceae	<i>Pterygota alata</i> (Roxb.) R. Br.	Yes	smooth
Ulmaceae	<i>Celtis tetrandra</i> Roxb.	No	smooth

**Figure Legend**

Figure 1. Relationship between height (m) and dbh (log cm) of trees with and without *Apis dorsata* nests in the two sites: Appankappu (all trees  $\geq 20\text{m}$  tall) and Bedaguli (all trees  $\geq 18\text{m}$  tall). Fitted line: solid = non-nesting trees, dashed = *Apis dorsata* nesting trees. Open circles=non-nesting trees and stars=nesting trees.
